Abstract. For many web sites, money earning is crucial for keeping the content production. Advertising is one of the most common strategies for web content monetization. To determine where is the more relevant place for ad location is an important task in order to get a gentle introduction of the commercial information. There are algorithms based on keywords appearing within text, however we consider that implicit meaning is more adequate for better harmony between content an advertising.

In this work we present a formal method which determines the best place for advertising location. For this, we explore the underlying tree like structure of a web page, we extract the text from each (X)HTML node and compute the semantic similarity (by employing latent semantic analysis) w.r.t., the advertising source text. We introduce a unique formula for the numerical calculation of the web page node relevance. We think it could be used for measuring the concordance among web page node and the commercial information and for the design of dynamic ads insertion methods.

Keywords. Semantic similarity, Latent Semantic Analysis, Dynamic advertising

1 Introduction

Advertising aggregation into web pages is a common strategy for monetization. Too many web sites deliver free content and get income by means of advertising payment, this kind of monetization allows them to operate and to keep the information production.

Sometimes advertising causes displeasure for diverse reasons, one for example, when the amount of publicity is excessive and other, when the commercial message is totally discordant with respect to the information read.

Advertising aggregation is an important issue which must be analyzed from different points of view. By one side, commercial information is necessary for guaranteeing economic survival of web sites. On the other side, users read information of their own interest, i.e., they browse and consume web content according to a specific motivation. We consider that methods that preserve the *thematic sense* between web content and an advertising message, can reduce the reader displeasure when publicity is shown.

In this work, we consider the thematic sense as a set of topics which are correlated. For instance an event of a football match, which is transmitted by TV, regularly is related with the consuming of snacks and beer and, perhaps, within a friends meeting. They are different facts, a football match, snacks and beer consuming and friends meeting, however they are correlated. A formal approach which is useful to find out correlations into data is the technique of Latent Semantic Analysis (LSA [5]).

Here we can state the proposal of this work, we think that a gentle introduction of the publicity can be reached if the sense of the web content with respect to the advertising message can be assured, for that, we introduce a formal method, in order to measure the level of correlation among both messages, expressed within text fragments.

Our proposal is motivated too, by the behavior of new styles of inread advertising which dynamically presents commercial information when an user browses a web page. In this way, web page fragments could be semantically compared with the advertising message and then, the more similar web page fragment could be determined for the publicity location.

Now an important issue must be faced, which web page fragments should be considered for the analysis?

We could to treat the text source as plain documents. However, web text is formatted using (X)HTML, i.e., the information is organized in formatting nodes which frequently provide certain implicit unity (all the information in a node is related) imposed by the web designer.

In this way, a main path for this work is going to be established in the context of approaches that exploit the text fragments within a web page and written in natural language, for instance those devoted to web filtering such as [2, 9, 17]. Regardless this focus, formulas here presented for calculus of semantic similarity among text fragments can be applied in a seamless way to any pair of text fragments, and thereby we could analyze sentences of paragraphs instead of web page text fragments.

We consider that methods preserving the unity of (X)HTML nodes are more acceptable. Some

works following this approach are [2, 6, 14, 16]. For instance, in [2] a method for information extraction from web pages considering the distance between (X)HTML nodes as measurement of analysis is introduced. However standard tests of similarity, in the setting of natural language processing, as a basis for producing text measurements are not employed. We believe that it is necessary to test classical techniques of natural language processing in order to establish an adequate comparison framework.

In this work we present a formal method for automatic measuring of semantic similarity among an advertising text and a web page node, based on techniques of similarity employed in natural language processing and inspired on the notion of latent semantic analysis. Our formal method requires only once the calculations of LSA and then it returns the more relevant web page node for advertising placement.

One of the main contributions of this paper is the definition of one formula to determine the semantic similarity of one text excerpt w.r.t. an advertising text. The formula is not affected by the size of text fragments.

The rest of the paper is organized as follows. In Section 2, Theoretical foundations of our work. In Section 3, we introduce a formal technique for relevance calculation based on semantic similarity and tree like structure of web pages. Then, in Section 5, we describe a prototype and a set of experiments. Finally, we present related work and conclusions in Section 6.

2 Theoretical foundations

In this section standard theoretical basis of our work are introduced.

The vector space model for automatic indexing was originally introduced by Salton et al., in [15] and it is considered a standard representation technique in information retrieval setting where stored entities (documents) are compared with each other. Given a text document d, a dictionary of terms is a set whose elements are the different words in the document d. $\overrightarrow{V}(d)$ denotes the vector associated to document d, whose components are the weights for each element in the dictionary. In a

vectorial representation, typographic symbols such as "," or "-" are ignored. The well known stop words are treated in the same way. For web pages, formatting labels are removed.

2.1 Latent Semantic Analysis

Latent Semantic Analysis (LSA) is a theory and technical method for extracting and representing the contextual-usage meaning of words by means of statistical computations applied to a large corpus of text [7]. Hence, the underlying idea is that the aggregate of all the word contexts in which a given word does and does not appear, provides a set of mutual constraints that largely determines the similarity of meaning of words and sets of words to each other [8].

First step of LSA consists of the construction of a matrix representation of text, i.e., the matrix M, in which columns are employed for modeling documents and rows for terms (words). Each row i represents a specific term as well as each column j represents a document. Thus, each cell $M_{i,j}$ stands for the frequency in which every term i appears in the document j. Term frequency tf can be substituted by some other weighting scheme as for instance tf.idf [10].

Next, LSA peforms the Singular Value Decomposition process (SVD) on the matrix M. the original matrix M, terms and documents are mutually dependent between them. In SVD, a rectangular matrix M is decomposed in the product of other three matrixes, i.e., $M = USV^{T}$. New matrixes will be formed by singular vectors or singular values. Resultant matrix U will contain a vector representation of the terms, which will have linear independency w.r.t. the relationship with the documents, while V will contain the vector representation of the documents whose components will be linearly independent w.r.t. the relationships with terms in M. Finally S is a diagonal matrix in which singular values are found in descendent order, and they represent the relationships between the other matrixes. highest values in S represent the relations with major variance among terms and documents.

After SVD decomposition, the original matrix ${\cal M}$ can be rebuilt as of the matrix product of the

resultant three matrixes. When a reconstruction over matrixes is performed it is possible to choose only the first k elements of the matrixes, i.e., $M' = U_k S_k V_k^T$, with this, a new matrix M' is obtained, in which the noise introduced by irrelevant relations is eliminated. Thus, the new values $M'_{i,j}$ unveil latent relationships among terms and documents, the so called human cognitive relations in [8]. SVD is implemented in many different mathematical tools, we use JAMA, a basic linear algebra package for Java [11].

Example 1 Let us consider the documents:

d0 = My computer. It has branded software.

d1 = A PC is useful. Only with branded software.

d2 = A PC (as computer) hardware. It can be generic.

d3 = Branded software and generic hardware. Both, go well with my computer.

The dictionary of the document collection is {computer, software, branded, PC, hardware, generic}. According to previous speech, the first row in M is for the representation of the term computer (second one for software, and so on w.r.t. the dictionary) and the column 0 will be for the first document, then $M_{0,3}$ stands for the number of times that computer appears in document 3, and so on. By applying the technique SVD, $M = USV^T$ is obtained:

$$M = \begin{bmatrix} 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix} U = \begin{bmatrix} 0.49 & 0.21 & 0.35 & 0.77 \\ 0.47 & -0.50 & 0.02 & -0.17 \\ 0.47 & -0.50 & 0.02 & -0.17 \\ 0.26 & 0.14 & -0.93 & 0.22 \\ 0.35 & 0.47 & 0.08 & -0.39 \\ 0.35 & 0.47 & 0.08 & -0.39 \end{bmatrix}$$

$$V = \begin{bmatrix} 3.19 & 0.0 & 0.0 & 0.0 \\ 0.0 & 1.74 & 0.0 & 0.0 \\ 0.0 & 0.0 & 1.19 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.6 \end{bmatrix} V T = \begin{bmatrix} 0.45 & 0.38 & 0.46 & 0.67 \\ -0.46 & -0.50 & 0.73 & 0.08 \\ 0.32 & -0.75 & -0.36 & 0.45 \\ 0.70 & -0.22 & 0.35 & -0.58 \end{bmatrix}$$

Considering k=2 and reconstructing M:

$$M' = \begin{bmatrix} 0.542 & 0.413 & 0.986 & 1.085 \\ 1.067 & 0.993 & 0.044 & 0.929 \\ 1.067 & 0.993 & 0.044 & 0.929 \\ 0.265 & 0.195 & 0.557 & 0.577 \\ 0.133 & 0.019 & 1.115 & 0.821 \\ 0.133 & 0.019 & 1.115 & 0.821 \end{bmatrix}$$

If the similarity between vectors representing the rows 0 and 3 of M is calculated, i.e., the comparison of similarity among terms "PC" and "computer", result is 0.4, while, 0.99 in M'.

Although the coincidence of both terms is given only in one document, correlations in the rest of documents allow to unveil the major latent similarity. This insights of relationships will be exploited later by the algorithms exposed in this document.

3 Calculating the more relevant web page node for advertising

Now, we describe the main contribution of this work, i.e., a formal technique for calculating the more relevant web page node for advertising.

The goal of the technique is to find out the web page node (of a specific URL) that presents the best semantic similarity w.r.t. a given advertising text. An *advertising text* is a fragment of text in natural language, which is regularly inserted in a web page to be exposed.

3.1 Semantic similarity based on LSA

Measuring the similarity of meanings between two blocks of text, on the one hand, the text of a fragment on a web page and on the other, the advertising text, can be defined as an act of measuring the semantic similarity between texts.

LSA is fully documented for comparison of similarity among documents of terms. However advertising placement requires being determined by analyzing several text pieces from a web page. In this setting a procedure for calculation of similarity among text excerpts (of variable size) instead of documents is needed.

Our approach for application of LSA through M^\prime and the discrimination of a set of text excerpts of different size implies several steps. We follow the same phases of [13] and some definitions, in order to define a unique formula for computing semantic similarity and its application towards web page fragments.

We require incorporate the semantic LSA information towards distinct sized texts and also, for the aggregation of the LSA semantic information upon the similarity calculation.

In this way, our first definition for semantic similarity measurement is called *relative similarity*: If a text fragment f_d from document d is being

analyzed, for each term i in collection we put in vector $\overrightarrow{V}(f_d)$ value 0 if that word does not appear in f_d , and we put value M'[i][d] if the word appears in f_d , i.e, the corresponding values in vector $\overrightarrow{V}(f_d)$ are mapped from column d in M'.

For instance, the vector for the text fragment f_{d_0} "It has branded software" from d_0 in the Example 1 is $\overrightarrow{V}(f_{d_0}) = \langle 0, 1.067, 1.067, 0, 0, 0 \rangle$. According to the dictionary {computer, software, branded, PC, hardware, generic}, terms "software" and "branded" appear in d_0 and their values are taken from M'[0][i]

Let us remember that we are computing similarities among text fragments of several size, this is the reason why we apply a mapping of values from document in M' to $\overrightarrow{V}(f_d)$, i.e., we do not take the whole document. We could use relative similarity for comparing text fragments, however, when there are not common terms in vectors, then result produced is 0. Hence, the strategy of relative similarity need to be improved.

We must consider that LSA gathers contextual information w.r.t. the terms in a collection. A certain kind of measurement of correlations should be conveniently incorporated into a new scheme of comparisons among text fragments. This is going to be examined in the the following.

Definition 2 (Mutual similarity matrix \mathcal{M}) Given the reconstructed matrix M', where m is the number of rows and n is the number of columns in M'. Let the squared $m \times m$ \mathcal{M} be the mutual similarity matrix. Such that $\mathcal{M}_{i,j}$ contains the similarity value $sim(\overrightarrow{V}(t_i), \overrightarrow{V}(t_j))$ where $\overrightarrow{V}(t_i) = \langle M'_{i,0}, \ldots, M'_{i,n-1} \rangle$, $i \in \{0, \ldots, m-1\}$ and $\overrightarrow{V}(t_j) = \langle M'_{i,0}, \ldots, M'_{i,n-1} \rangle$ with $j \in \{0, \ldots, m-1\}$.

Intuitively speaking \mathcal{M} is a data structure which contains the cosine similarity values between all the terms in the reconstructed matrix M'.

Example 3 Let us consider the Example 1, the mutual similarity matrix of M' is as follows:

$$\mathcal{M} = \left[\begin{array}{cccccccc} 1.000 & 0.730 & 0.730 & 0.999 & 0.920 & 0.920 \\ 0.730 & 1.000 & 1.000 & 0.692 & 0.405 & 0.405 \\ 0.730 & 1.000 & 1.000 & 0.692 & 0.405 & 0.405 \\ 0.999 & 0.692 & 0.692 & 1.000 & 0.940 & 0.940 \\ 0.920 & 0.405 & 0.405 & 0.940 & 1.000 & 1.000 \\ 0.920 & 0.405 & 0.405 & 0.940 & 1.000 & 1.000 \\ \end{array} \right]$$

Here $\mathcal{M}[4][5]=1.000$ which is the result of similarity among term 4 and 5 in M', i.e., the similarity between hardware, in the row 4, and generic, in the row 5 of M'. This is due to both terms appear always in pair in the documents of Example 1. Similarities between computer and PC are more obvious. Consequently diagonal matrix is composed by only ones.

In the matrix of mutual similarities the information that shows explicitly the numerical similarities among terms in a collection of documents is located. Now, it is necessary to exploit such measures from ${\mathcal M}$ to compute the calculus of similarity of small fragments of text and guaranteeing that term correlations are taken into account.

For this, we apply a simple idea: if a term t0 is highly related (closer to one) with term t4 according to $\mathcal M$ and, if we have a text fragment f which contains t0 and does not contain t4 then, in order to execute the calculation of similarity of f we will aggregate to the vector $\overrightarrow{V}(f)$ the values for t0 and also for t4, i.e., $\overrightarrow{V}(f) = \langle 1,0,0,0,threshold \rangle$ where threshold is an arbitrary value in order to identify the limit for considering a meaningful relation between terms. Formally:

Definition 4 (threshold, meaningful relation)

Let the real number μ be threshold such that $0<\mu\leq 1$, and $\mathcal{M}_{i,j}$ is a meaningful relation between terms t_i and t_j in $M'\Longleftrightarrow \mathcal{M}_{i,j}\geq threshold$, where $i,j\in\{0,\ldots,m-1\}$ and m is the number of rows in M'.

Basically, threshold define the least numerical limit of similarity measure for considering a relation between terms as important. Each row in M' represents a term in the collection of documents, and the numerical relation between the terms $t_i,\,t_j$ is joined in $\mathcal{M}_{i,j}$

In order to incorporate main correlations in the vectors of text fragments we define the concept of augmented vector.

Definition 5 (augmented vector) Let $\overrightarrow{V\triangle}(f)$ be the augmented vector of a text fragment f in the setting of a collection of documents, such that $\overrightarrow{V\triangle}(f) = \langle v_0, \dots, v_{m-1} \rangle$ where v_i is the corresponding weight of $t_i \in dict(collection)$ in the fragment f, which is obtained from:

$$v_i = \begin{cases} \textit{weight}(t_i, f) & \textit{if } t_i \in dict(f) \\ \textit{threshold} & \textit{if } t_i \notin dict(f) \textit{ but there is a} \\ & \textit{meaningful relation with} \\ & \textit{some } t_j \in dict(f) \\ \textit{0} & \textit{otherwise} \end{cases}$$

Where $i, j \in \{0, ..., m-1\}$, m is the number of rows in M' and $weight(t_i, f)$ is a function that returns the corresponding weight of t_i in f.

When a vector is augmented, not only appears the weight of those terms present in a fragment of text, also, the threshold value is incorporated in the position corresponding for terms which are not present in the fragment but, they maintain a correlation (meaningful relation) with some other terms present in the fragment. Roughly speaking, in an augmented vector there are values for its terms and for their correlated terms. Now, for computing similarity we overload standard cosine similarity.

Definition 6 (augmented similarity) The augmented similarity between fragments of text t_1 , t_2 is defined by $augsim(t_1,t_2) = \frac{\overrightarrow{V} \overrightarrow{\triangle}(t_1) \cdot \overrightarrow{V} \overrightarrow{\triangle}(t_2)}{|\overrightarrow{V} \overrightarrow{\triangle}(t_1)||\overrightarrow{V} \overrightarrow{\triangle}(t_2)|}$

where the numerator represents the dot product of the augmented vectors $\overrightarrow{V\Delta}(t_1)$ and $\overrightarrow{V\Delta}(t_2)$, and the denominator is the product of their Euclidean lengths.

Here, augmented similarity returns the similarity calculus of two vectors, which were augmented from correlations among terms.

Finally with the goal of harvesting the best properties of relative similarity and augmented similarity we define semantic similarity.

Definition 7 (semantic similarity) Given t1 and t2, and $compsim(t_1, t_2) = log(relsim(t_1, t_2) + 0.001) + log(augsim(t_1, t_2) + 0.001)$, let

$$semsim(t_1,t_2) = \frac{1}{1 + e^{-compsim(t_1,t_2)}}$$

be the semantic similarity between text fragments t_1 and t_2 .

Fundamentally we apply the product of relative similarity with augmented similarity, which we call compsim. Relative similarity, has two graceful properties, in one hand, it takes advantage of LSA correlations and on the other hand, it computes greater values in the case of presence of common terms. Them, an initial idea is to compute the product of relsim and augsim, however, eventually the calculus could produce 0, to redress this, we apply a logarithmic addition. Finally, in order to normalize the values of calculations in the range of 0 and 1, we introduce the well known sigmoid function i.e., $f(x) = 1/(1 + e^{-x})$ where x is our compsim.

In this way, semantic similarity combines properties of both measurements. Relative similarity is more affected by coincidence of terms in the *ad text* w.r.t. the analyzed fragment, while augmented similarity offers greater values when a text fragment brings more relationships with its own terms, in other words, it privileges amount of correlations of its terms.

At this point, an useful formal scheme for computing semantic similarity between text fragments has been completely defined. Next a set of rules for text fragmentation in order to determine the more relevant text from a web page, is required.

4 Extraction of text fragments from a web page

In order to define a strategy to extract text fragments from a web page, we could suggest many criteria. However there is the standard scheme DOM, which organizes the content of a web page in hierarchical nodes.

DOM model is an adequate scheme, it stands for Document Object Model, which is a W3C standard

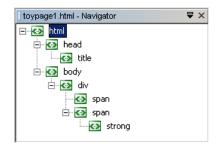

Fig. 1. The DOM tree of Example 8, visualized in a graphical way.

platform—and language—neutral interface that allows programs and scripts to dynamically access and update the content, structure and style of documents [1].

Example 8 Let us consider the following web page:

```
<html>
<head>
   <title>Semantics within web pages</title>
</head>
<body>
  Semantics is related with meaning.
  <div>
    Semantics can be extracted in two ways:
    <span>
      a) Driven by metadata
    </span>
    <span>
      b) By using mathematical techniques.
          One of them is:
          <strong>
                  latent semantic analysis.
          </strong>
    </span>
  </div>
</body>
</html>
```

Its corresponding DOM representation is visualized in a graphical mode in Figure 1. We can see a web page as a tree-like data structure where each node is an (X)HTML element, i.e., a (X)HTML tag with its contained text and its attributes, furthermore, its children are the embedded (X)HTML labels.

In a DOM data structure, if a node contains nested (X)HTML labels, there is a relation of *embedding* between the node and its children. For instance in Example 8, div node embeds two span node children.

Definition 9 (web page tree) A web page tree $(\mathcal{V}, \mathcal{E})$ is a directed, acyclic graph whose vertices \mathcal{V} are (X)HTML elements and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is a set of ordered pairs $(v \to v') \in \mathcal{E}$ called edges, where v embeds v', and there is a $root(\mathcal{V}, \mathcal{E})$ node which is not embedded.

Given a web page tree $P=(\mathcal{V},\mathcal{E})$ and two nodes $v_1,v_n\in\mathcal{V},$ if there is a sequence v_1,v_2,\ldots,v_n of nodes in P where $(v_i,v_{i+1})\in\mathcal{E}$ for $1\leq i\leq n-1,$ then we say that there is a *path* from v_1 to v_n in P. Given $u,v\in\mathcal{V}$ we say that the node v is *reachable* from v if there is a path from v to v. We use v to denote the reflexive and transitive closure of v.

Now we define candidate branch of a web page tree in order to compute semantic similarity tests w.r.t. the web user query.

Definition 10 (candidate branch) Let $P = (\mathcal{V}, \mathcal{E})$ be a web page tree, then $B = (\mathcal{V}', \mathcal{E}')$ is a candidate branch where $\mathcal{V}' = \{v \in \mathcal{V} | v \neq root(P)\} \cup \{w | w \text{ is reachable from } v\}$ and $\mathcal{E}' = \{(u_1, u_2) | (u_1, u_2) \in \mathcal{E}, \text{ and } u_1, u_2 \in \mathcal{V}'\}$

Hence, each node (except the root) of a web page tree and its children is a candidate branch.

Definition 11 (web text) Let $B = (\mathcal{V}, \mathcal{E})$ be a candidate branch, then text(B) is its web text.

Web text is necessary to get text excerpts for applying semantic similarity calculations.

Example 12 Let us consider the web page tree of Example 8, then there are 7 candidate branches, i.e., those which are compound by the following (X)HTML elements:

```
\begin{split} &B_1 \!=\! \{\text{head, title}\}\\ &B_2 \!=\! \{\text{title}\}\\ &B_3 \!=\! \{\text{body, div, span}_1, \text{span}_2, \text{strong}\}\\ &B_4 \!=\! \{\text{div, span}_1, \text{span}_2, \text{strong}\}\\ &B_5 \!=\! \{\text{span}_1\}\\ &B_6 \!=\! \{\text{span}_2, \text{strong}\} \end{split}
```

B₇={strong}

Their contained texts were not drawn. Hence, the set of candidate branches is $\{B_1, B_2, B_3, B_4, B_5, B_6, B_7\}$, and with respect to the function text, for instance, text(B_6) returns the text excerpt "By using mathematical techniques. One of them is: latent semantic analysis." and text(B_7) returns the string: "latent semantic analysis.", i.e., we extract the text without (X)HTML labels.

Definition 13 (semantically relevant nodes)

Given $L = \{ < B, s > | B \text{ a candidate branch, } A \text{ an advertising text and } s = semsim(text(B), A) \}$ be the ordered set of semantically relevant nodes induced by the total order \succeq where $< B_x, s_x > \succeq < B_y, s_y > \text{if } s_x \geq s_y.$

Example 14 Here the shape of the semantically relevant nodes is basically an ordered list composed by candidate branches and their corresponding semantic similarity w.r.t. an ad text, for instance: $L = \{<\{span_2,...\},0.53>$, $<\{div,...\},0.5>$, $<\{body,...\},0.42>$, $<\{span_1\},0.28>$, $<\{strong\},0.28>$, $<\{body,...\},0.0>$, would show the branches (without text drawing) and their semantic similarity.

Once semantically relevant nodes of a web page were computed, we are able to offer the most significant text excerpts as a result of an *ad text*.

Next we present a definition of *relevant web page node* for advertising placement, for this, we require some auxiliary functions: highest(L) returns the web page node with greater semantic similarity found in a set of semantically relevant nodes, in the above example the function would return $< \{span_2, \ldots\}, 0.53 >$. Formally,

Definition 15 (relevant web page node) Given a web page url and an advertising text A, let node = highest(L) be the more relevant web page node for advertising placement, where L are the semantically relevant nodes of url with respect to A.

In Figure 2 we present an algorithm to determine the more relevant web page node for advertising location from a given web page.

The first step of the algorithm prepares a collection from contextual documents, then constructs the matrix M by indexing text from the collection, next computes singular value decomposition, reconstructs M' and calculates the mutual similarity matrix M, once this was done, it has all elements for computing semantic similarity between nodes and advertising text. There, we introduce a function: $semantically_relevant_nodes(w, A)$ which computes the list of semantically relevant nodes from a particular web page and by considering A as text advertising.

The last part of the algorithm extracts the highest semantically related web page node w.r.t. the advertising text and returns it. In other words, the algorithm determines which web page node has more semantic similarity w.r.t. an advertising text.

5 Prototype and experiments

In this section, some aspects of the practical approach for web page node relevance calculation are presented, a relevant node is the more semantically related w.r.t. a text advertising. The computational tool is shown in Figure 3.

Once target web page is defined, the web page is downloaded, for this, a parser is employed. Jericho [12] allows to retrieve and to filter web pages and their text. Inclusive it is possible to walk through their tree structures, visiting each node and recovering their text. DOM node tree is visited in order to take one node, each time, for analysis. Then, DOM node and advertising text are augmented and finally a value of semantic similarity is computed. Node that presents highest semantic similarity is chosen as the more relevant place for the particular commercial information.

Figure 4 is devoted for natural language processing phase explanation. First step refers to text preparation, naturally, the tool requires a set of documents whose content must be in the same context than text advertising. This is important because LSA will calculate correlations between terms, which is useful for measuring semantically

related texts, and to be exploited in our relevance analysis.

Then, the standard actions of natural language processing are shown: text cleaning, stop words deleting, and so on. For that phase, a proper library has been developed. Each document is treated, next, matrix M is formed by indexing text from the collection of documents. SVD calculus is performed by using a library of third part, M' is reconstructed and the mutual similarity matrix is computed. Roughly speaking this process performs latent semantic analysis.

5.1 Experiments

In this section we describe an experiment performed upon the prototype, and correspondingly upon the formal technique. The collection was composed by text documents from a set of web pages whose links are the following.

- 1. http://lsa.colorado.edu/whatis.html
- 2. https://en.wikipedia.org/wiki/
 Latent_semantic_analysis
- 3. http://recommender-systems.org/
 latent-semantic-indexing/

In this experiment, all web pages compose the collection of documents for LSA feeding. Next, we employ a little paragraph of text advertising in order to determine the more semantically related web page node (in each url), i.e., the more relevant node for advertising placement.

Each web page was downloaded, and their DOM nodes were extracted by means of our DOM parser (based on Jericho [12]), then a text file with the set of nodes from each URL was prepared. Next, the whole process of the formal technique introduced in Section 3 was computed in order to determine semantic similarity of every node and as a consequence the more adequate place for commercial information.

The advertising text is: singular value decomposition (SVD) to the matrix, for this we developed a tool that receives a text and returns each text fragment and its corresponding measurements. Thereby the decision is taken by considering the web page node with highest semantic similarity.

```
Input: U a set of contextual documents; w the target web page
for advertising; A, an advertising text; k dimensions for matrix
reconstruction
Output: node, the relevant web page node
Initialization: Collection := \{\}
Begin
  For each u \in U
       let d_u := text(u)
       Collection := Collection \cup \{d_u\}
  \mathbf{let}\ M \coloneqq \mathbf{indexing}\ \mathbf{as}\ \mathbf{of}\ Collection
  let USV^T := SVD(M)
  \mathbf{let}\ M' := U_k S_k V_k^T
  let \mathcal{M} := mutual similarity matrix of M'
  let L_w := semantically\_relevant\_nodes(w, A)
  let node := highest(L_w)
End
Return: node
```

In the Table 1 a set of measurements are presented, there, a series of 26 nodes f from http://lsa. colorado.edu/whatis.html are put through testing.

The first calculus shown is sim which represents the standard cosine similarity between the ad text an the analyzed node. The second one is the result of the relative similarity relsim, the third one represents the augmented similarity Next column presents results of augsem. composed compsim similarity, i.e., the product of relative and augsem, then semsim iscalculated by using the logarithmic approach. semsim unveils the result of the query, i.e., fragment 22 from the http://lsa.colorado.edu/ whatis.html URL. For each node of web page the maximum semantic similarity w.r.t. the ad text is calculated and then the best location for advertising is discovered.

Now let us focus in a series of properties of the technique and let us observe its behavior through the results in the Table 1.

The technique is independent of the size of the text node analyzed. Initially it is easier computing calculations in simple documents than in complete documents (or web pages). DOM nodes present phenomenon of embedding, for instance node body embeds all the paragraphs in a web page. Fragment 1 constitutes the biggest node in http://lsa.colorado.edu/whatis.html and, nevertheless it does not bring the highest semsim.

The technique offers maximum qualification for keyword coincidences. In column semsim, maximum values are those that present relsim different of 0, i.e., there is keyword shared in analyzed node and ad text. If there is not common keywords the discriminating values will be those from augsim. And some interesting, we can obtain results inclusive when nodes do not contain common terms.

The technique exploits LSA results. augsim determines a nice measurement among text fragments. Each vector is enriched with meaningful relationships of terms. Hence augsim calculates the quality of correlations between terms. Let us observe the fragment number 5, its text is short, however the word information appears more than 40 times in

https://en.wikipedia.org/wiki/ Latent_semantic_analysis, this is the reason why its measurements are higher in Table 1.

6 Related work and conclusions

To the best of our knowledge, there are many research works focused on measuring the success of advertising campaigns [3, 4], however there are not for measuring the best place for publicity location in a web page. May be, this concern is more attractive for companies and solutions they reach are implemented instead of published. However from an academic point of view it is interesting to measure the meaning of advertising w.r.t. the meaning of the web content which an user reads. In this work we proposed a method for the numerical comparison, other future work will be devoted to analyze the success of this criteria for publicity location.

In summary, we have introduced a formal technique for semantic similarity between web page nodes and advertising messages, which presents several advantages: always returns a value, is independent of the size of text fragments, privileges (numerically) the existence of common words in text node and ad text, outperforms results of cosine similarity, only once calculation of LSA is required to produce any number of comparisons from an ad text. The exposed formula of semantic similarity is based on that presented in [13], some formalizations are included here. And finally, the technique is described in a technological style (fully procedural) which is convenient to replicate the tool.

We have developed a pair of tools, one for web page (Jericho [12] based) parsing and other for text fragment ranking (Figure 5).

For future work, we are testing deep methods based on word embedding, in order to produce a parametric framework for web filtering and web indexing.

The potential applications of the technique are the following: analysis of similarity among content and advertising, filtering of web pages (since we rank DOM nodes with semantic similarity), transformation of web pages, determining of hot sections in a web page, production of industrial tools, and other more.
